The rapidly expanding body of available genomic and protein structural data provides a rich resource for understanding protein dynamics with biomolecular simulation. While computational infrastructure has grown rapidly, simulations on an omics scale are not yet widespread, primarily because software infrastructure to enable simulations at this scale has not kept pace. It should now be possible to study protein dynamics across entire (super)families, exploiting both available structural biology data and conformational similarities across homologous proteins. Here, we present a new tool for enabling high-throughput simulation in the genomics era. Ensembler takes any set of sequences—from a single sequence to an entire superfamily and shepherds them through various stages of modeling and refinement to produce simulation-ready structures. This includes comparative modeling to all relevant PDB structures (which may span multiple conformational states of interest), reconstruction of missing loops, addition of missing atoms, culling of nearly identical structures, assignment of appropriate protonation states, solvation in explicit solvent, and refinement and filtering with molecular simulation to ensure stable simulation. The output of this pipeline is an ensemble of structures ready for subsequent molecular simulations using computer clusters, supercomputers, or distributed computing projects like Folding@home. Ensembler thus automates much of the timeconsuming process of preparing protein models suitable for simulation, while allowing scalability up to entire superfamilies. A particular advantage of this approach can be found in the construction of kinetic models of conformational dynamics—such as Markov state models (MSMs)—which benefit from a diverse array of initial configurations that span the accessible conformational states to aid sampling. We demonstrate the power of this approach by constructing models for all catalytic domains in the human tyrosine kinase family, using all available kinase catalytic domain structures from any organism as structural templates.

Ensembler is free and open source software licensed under the GNU General Public License (GPL) v2. It should run on all major operating systems, and has been tested on Linux and OS X. The latest release can be installed via the conda package manager, and the latest source can be downloaded from https://github.com/choderalab/ensembler.

Keywords: molecular dynamics simulation; comparative modeling; distributed simulation

I. INTRODUCTION

Recent advances in genomics and structural biology have helped generate an enormous wealth of protein data at the level of amino-acid sequence and three-dimensional structure. However, proteins typically exist as an ensemble of thermally accessible conformational states, and static structures provide only a snapshot of their rich dynamical behavior. Many functional properties—such as the ability to bind small molecules or interact with signaling partners—require transitions between states, encompassing anything from reorganization of sidechains at binding interfaces to domain motions to large scale folding-unfolding events. Drug discovery could also benefit from a more extensive consideration of protein dynamics, whereby small molecules might be selected based on their predicted ability to bind and trap a protein target in an inactive state [1].

Molecular dynamics (MD) simulations have the capabilMolecular dynamics (MD) simulations have the capabilMolecular dynamics (MD) simulations have the capabilty, in principle, to describe the time evolution of a protein in atomistic detail, and have proven themselves to be
useful tool in the study of protein dynamics. A number of mature software packages and forcefields are now available, and much recent progress has been driven by advances in computing architecture. For example, many MD

29 packages are now able to exploit GPUs [2, 3], which pro-30 vide greatly improved simulation efficiency per unit cost rel-31 ative to CPUs, while distributed computing platforms such 32 as Folding@home [4], Copernicus [5], and GPUGrid [6], al-33 low scalability on an unprecedented level. In parallel, meth-34 ods for building human-understandable models of protein 35 dynamics from noisy simulation data, such as Markov state modeling (MSM) approaches, are now reaching maturity [7– ³⁷ 9]. MSM methods in particular have the advantage of be-38 ing able to aggregate data from multiple independent MD 39 trajectories, facilitating parallelization of production simu-40 lations and thus greatly alleviating overall computational 41 cost. There also exist a number of mature software packages 42 for comparative modeling of protein structures, in which a 43 target protein sequence is modeled using one or more struc-44 tures as templates [10, 11].

However, it remains difficult for researchers to exploit the full variety of available protein sequence and structural data in simulation studies, largely due to limitations in software architecture. For example, the set up of a biomolecular simulation is typically performed manually, encompassing a series of fairly standard (yet time-consuming) steps such as the choice of protein sequence construct and starting structure(s), addition of missing residues and atoms, solvation with explicit water and counterions (and potentially buffer components and cosolvents), choice of simulation parameters (or parameterization schemes for components where

^{*} Corresponding author; john.chodera@choderalab.org

minimization, and one or more short preparatory MD sim- 115 URL of where to get the code and TK models here?] ulations to equilibrate the system and relax the simulation cell. Due to the laborious and manual nature of this process, simulation studies typically consider only one or a few proteins and starting configurations. Worse still, studies (or collections of studies) that do consider multiple proteins often suffer from the lack of consistent best practices in this preparation process, making comparisons between related proteins unnecessarily difficult.

The ability to fully exploit the large quantity of available protein sequence and structural data in biomolecular simulation studies could open up many interesting avenues for research, enabling the study of entire protein families or superfamilies within a single organism or across multiple organisms. The similarity between members of a given protein family could be exploited to generate arrays of conformational models, which could be used as starting configurations to aid sampling in MD simulations. This approach would be highly beneficial for many MD methods, such as MSM construction, which require global coverage of the conformational landscape to realize their full potential, and would also be particularly useful in cases where structural data is present for only a subset of the members of a protein family. It would also aid in studying protein families known to have multiple metastable conformations—such as kinases—for which the combined body of structural data for the family may cover a large range of these conformations, while the available structures for any individual member might encompass only one or two distinct conformations.

Here, we present the first steps toward bridging the gap between biomolecular simulation software and omicsscale sequence and structural data: a fully automated open source framework for building simulation-ready protein models in multiple conformational substates scalable from single sequences to entire superfamilies. **Ensembler** provides functions for selecting target sequences and homologous template structures, and (by interfacing with a number of external packages) performs pairwise alignments, comparative modeling of target-template pairs, and several stages of model refinement. As an example application, we have constructed models for the entire set of human tyrosine kinase catalytic domains, using all available structures of protein kinase domains (from any species) as templates. This results in a total of almost 400,000 models, and we demonstrate that these provide wide-ranging coverage of known functionally relevant conformations. By using these models as starting configurations for highly parallel MD simulations, we expect their structural diversity to greatly aid in sampling of conformational space.

number of other ways. For example, the generated models could represent valuable data sets even without subtural data for a given protein family. Furthermore, the au- 163 ular expression could be used: 'Protein kinase(?!; tomation of simulation set up provides an excellent oppor- 164 truncated) (?!; inactive). In this case, target identi-

DESIGN AND IMPLEMENTATION

Ensembler is written in Python, and can be used via a command-line tool (ensembler) or via a flexible Python API 119 to allow integration of its components into other applica-

The **Ensembler** modeling pipeline comprises a series of 122 stages which are performed in a defined order. A visual overview of the pipeline is shown in Fig. 1. The various stages of this pipeline are described in detail below.

Target selection and retrieval

The first stage entails the selection of a set of target protein sequences—the sequences the user is interested in generating simulation-ready structural models for. This may be 129 a single sequence—such as a full-length protein or a con-130 struct representing a single domain—or a collection of sequences, such as a particular domain from an entire family of proteins. The output of this stage is a FASTA-formatted text file containing the desired target sequences with corresponding arbitrary identifiers.

The ensembler command-line tool allows targets to be selected from UniProt—a freely accessible resource for protein sequence and functional data (uniprot.org) [12]— 138 via a UniProt search guery. To retrieve target sequences 139 from UniProt, the subcommand gather_targets us used with the --query flag followed by a UniProt query string conforming to the same syntax as the search function 142 available on the UniProt website. For example, --query 'mnemonic:SRC_HUMAN' would select the full-length 144 human Src sequence, while --query 'domain: "Protein 145 kinase" AND taxonomy: 9606 AND reviewed: yes' would select all human protein kinases which have been reviewed by a human curator. In this way, the user may select 148 a single protein, many proteins, or an entire superfamily 149 from UniProt. The program outputs a FASTA file, setting the 150 UniProt mnemonic (e.g. SRC_HUMAN) as the identifier for 151 each target protein.

In many cases, it will be desirable to build models of 153 an isolated protein domain, rather than the full-length protein. The gather_targets subcommand allows pro-155 tein domains to be selected from UniProt data by pass-156 ing a regular expression string to the --domains flag. 157 For example, the above --query flag for selecting all We anticipate that the tool will prove to be useful in a 158 human protein kinases returns UniProt entries with do-159 main annotations including "Protein kinase", "Protein kinase 1", "Protein kinase 2", "Protein kinase; truncated", sequent production simulation, allowing exploration of the 👊 "Protein kinase; inactive", "SH2", "SH3", etc. To select conformational diversity present within the available struc- 162 only domains of the first three types, the following reg-113 tunity to make concrete certain "best practices", such as the 165 fiers are set with the form [UniProt mnemonic]_D[domain

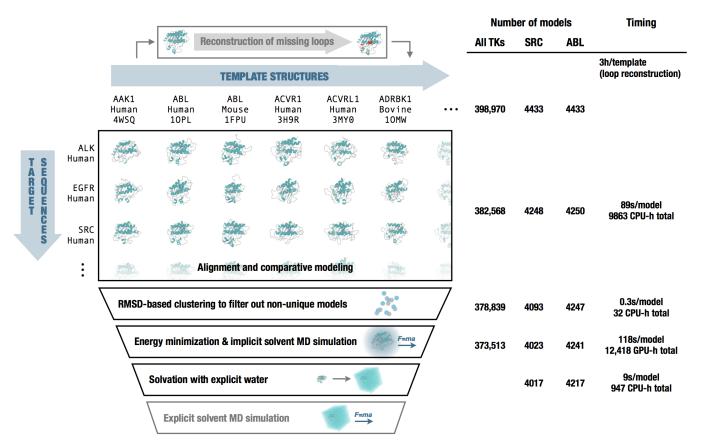

FIG. 1. Diagrammatic representation of the various stages of the Ensembler pipeline and illustrative statistics for modeling all human tyrosine kinase catalytic domains. On the left, the various stages of the Ensembler pipeline are shown. On the right, the number of viable models surviving each stage of the pipeline is shown for modeling all 90 tyrosine kinases (All TKs) and representative individual tyrosine kinases (SRC and ABL). Typical timings on a computer cluster (containing Intel Xeon E5-2665 2.4GHz hyperthreaded processors and NVIDIA GTX-680 or GTX-Titan GPUs) is reported to illustrate resource requirements per model for modeling the entire set of tyrosine kinases. Note that CPU-h denotes the number of hours consumed by the equivalent of a single CPU hyperthread and GPU-h on a single GPU—parallel execution via MPI reduces wall clock time nearly linearly.

Target sequences can also be defined manually (or from 189 another program) by providing a FASTA-formatted text file arbitrary identifiers.

Template selection and retrieval

174

The ensembler gather_templates subcommand procontain multiple domains of interest (e.g. JAK1_HUMAN_DO, 187 vides methods for selecting template structures from either UniProt or the PDB (http://www.rcsb.org/pdb), specified by the --gather_from flag. Both methods select templates at the level of PDB chains—a PDB structure containcontaining the desired target sequences with corresponding ing multiple chains with identical sequence spans (e.g. for 192 crystal unit cells with multiple asymmetric units) would thus 193 give rise to multiple template structures.

Selection of templates from the PDB simply requires 195 passing a list of PDB IDs as a comma-separated string, e.g. --query 2H8H,1Y57. Specific PDB chain IDs can Ensembler uses comparative modeling to build models, 197 optionally also be selected via the --chainids flag. and as such requires a set of structures to be used as tem- 198 The program retrieves structures from the PDB server, plates. The second stage thus entails the selection of tem- 199 as well as associated data from the SIFTS service plates and storage of associated sequences, structures, and 200 (www.ebi.ac.uk/pdbe/docs/sifts) [13], which provides dentifiers. These templates can be specified manually, or 201 residue-level mappings between PDB and UniProt entries. using the ensembler gather_templates subcommand to 202 The SIFTS data is used to extract template sequences, automatically select templates based on a search of the 203 retaining only residues which are resolved and match Protein Data Bank (PDB) or UniProt. A recommended ap- 204 the equivalent residue in the UniProt sequence—nonproach is to select templates from UniProt which belong to 205 wildtype residues are thus removed from the template 184 the same protein family as the targets, guaranteeing some 206 structures. Furthermore, PDB chains with less than a

given percentage of resolved residues (default: 70%) are 262 residues spans are modeled in the subsequent stage. filtered out. Sequences are stored in a FASTA file, with identifiers of the form [UniProt mnemonic]_D[UniProt domain index]_[PDB ID]_[PDB chain ID], SRC_HUMAN_DO_2H8H_A. Matching residues tracted from the original coordinate files and stored as PDB-format coordinate files.

Selection of templates from UniProt proceeds in a similar fashion as for target selection; the --query flag is used to select full-length proteins from UniProt, while the optional -domains flag allows selection of individual domains with regular expression string. The returned UniProt data for each protein includes a list of associated PDB chains and their residue spans, and this information is used to select template structures, using the same method as for template selection from the PDB. Only structures solved by X-ray crystallography or NMR are selected, thus excluding computergenerated models available from the PDB. If the --domains flag is used, then templates are truncated at the start and end of the domain sequence.

Templates can also be defined manually. Manual specification of templates simply requires storing the sequences and identifiers in a FASTA file, and the structures as PDBformat coordinate files with filenames matching the identifiers in the sequence file. The structure residues must also match those in the sequence file.

Template refinement

233

234

Unresolved template residues can optionally be modeled into template structures with the loopmodel subcommand, which employs a kinematic closure algorithm provided via the loopmodel tool of the Rosetta software suite [14, 15]. Because fewer loops need to be built during the subsequent target model-building stage, we find that prebuilding template loops tends to provide higher-quality models after 295 given value. completion of the **Ensembler** pipeline. [JDC: Should we cite 296 aim a bit to say that it is possible this could make things asier?] [DLP: Sikander mentioned to me that someone has developed an algorithm called pokefind (or knotfind, in proteins, of the type which encouraged us to use Rosetta to reconstruct template loops. DOI: 10.1093/bioinformatics/btp198 It sounds like these algorithms have actually been implemented in Rosetta, so this could explain why Rosetta seems to do better at avoiding making these knotted structures. Would be useful to check this out further first, and then decide whether or not to discuss the knotted structures in the manuscript.]

Loop remodeling may fail for a small proportion of templates due to spatial constraints imposed by the original 308 structure; the subsequent modeling step thus automati- 309 PDB structures as individual templates, a number of modcally uses the remodeled version of a template if available, 310 els may be generated with very similar structures if these but otherwise falls back to using the non-remodeled ver- individual chains are nearly identical in conformation. Modeling

In the modeling stage, structural models of the target se-265 quence are generated from the template structures, with the goal of modeling the target in a variety of conforma-267 tions that could be significantly populated under equilib-268 rium conditions.

Modeling is performed using the automodel function of 270 the Modeller software package [16, 17] to rapidly generate 271 a single model of the target sequence from each template 272 structure. Modeller uses simulated annealing cycles along 273 with a minimal forcefield and spatial restraints—generally 274 Gaussian interatomic probability densities extracted from 275 the template structure with database-derived statistics determining the distribution width—to rapidly generate candidate structures of the target sequence from the provided template sequence [16, 17].

While Modeller's automodel function can generate its 280 own alignments automatically, a standalone function was preferable for reasons of programming convenience. As such, we implemented pairwise alignment functionality using the the BioPython pairwise2 module [18]—which uses ²⁸⁴ a dynamic programming algorithm—with the PAM 250 scor-285 ing matrix of Gonnet et al. [19]. The alignments are car-286 ried out with the align subcommand, prior to the model-287 ing step which is carried out with the build_models subcommand. The align subcommand also writes a list of the sequence identities for each template to a text file, and this can be used to select models from a desired range of sequence identities. The build_models sub-292 command and all subsequent pipeline functions have a 293 --template_seqid_cutoff flag which can be used to select only models with sequence identities greater than the

Models are output as PDB-format coordinate files. To ur evidence for this with the TKs, or maybe tone back the 297 minimize file storage requirements, **Ensembler** uses the 298 Python gzip library to apply compression to all sizeable text files from the modeling stage onwards. The restraints used by Modeller could potentially be used in alternative addiwhich I think is an earlier version) which aims to find knots 301 tional refinement schemes, and Ensembler thus provides 302 a flag (--write_modeller_restraints_file) for option-303 ally saving these restraints to file. This option is turned off by $_{
m 304}$ default, as the restraint files are relatively large (e.g. \sim 400 305 KB per model for protein kinase domain targets), and are not expected to be used by the majority of users.

Filtering of nearly identical models

Because **Ensembler** treats individual chains from source model missing residues at the termini of a structure—such 313 versity if they so choose, **Ensembler** provides a way to filtain only a single model per cluster.

Refinement of models

324

While the utility of comparative modeling methods has 381 325 been greatly enhanced by the recent explosion in the availability of protein structural data, the structures generated 382 are generally considered "low-resolution" in comparison to as sidechain orientation [27].

Ensembler thus includes a refinement module, which 396 uses short molecular dynamics simulations to refine the 397 models built in the previous step. As well improving model molecules, if desired.

the L-BFGS algorithm [28], followed by a short molecular dynamics (MD) simulation with an implicit solvent representation. This is implemented using the OpenMM molecular simulation toolkit [2], chosen for its flexible Python API, and high performance GPU-acclerated simulation code. The simulation is run for a default of 100 ps, which in our example applications has been sufficient to filter out poor models (i.e. those with atomic overlaps unresolved by energy minimization, which result in an unstable simulation), as well as helping to relax model conformations. As discussed in the Results section, our example application of the **Ensembler** the vast majority failed within the first 1 ps of simulation.

The simulation protocol and default parameter values have been chosen to represent current "best practices" for the refinement simulations carried out here. As such, the simulation is performed using Langevin dynamics, with a default force field choice of Amber99SB-ILDN [29], 418 along with a modified generalized Born solvent model [30] 419 can be used to prepare models for other uses.

314 ter out models that are very similar in RMSD. The cluster 369 the other force fields or implicit water models implesubcommand can thus be used to identify models which dif- 370 mented in OpenMM can be specified using the --ff and fer from other models in terms of RMSD distance by a user- 371 --water_model flags respectively. The simulation length specified cutoff. Clustering is performed using the regular 372 can also be controlled via the --simlength flag, and many spatial clustering algorithm [8], as implemented in the MSM- 373 other important simulation parameters can be controlled Builder Python library [20], which uses mdtraj [21] to calcu- 374 from either the API or CLI (via the --api_params flag). The late RMSD (for C_{α} atoms only) with a fast quaternion char- 375 default values are set as follows—timestep: 2 ps; temperacteristic polynomial (QCP) [22-24] implementation. A min- 376 ature: 300 K; Langevin collision rate: 20 ps⁻¹; pH (used imum distance cutoff (which defaults to 0.6 Å) is used to re- 377 by OpenMM for protonation state assignment): 7. We also 378 draw attention to a recent paper which indicates that lower Langevin collision rates may result in faster phase space ex-380 ploration [31].

Solvation and NPT equilibration

While protein-only models may be sufficient for struc-383 tural analysis or implicit solvent simulations, **Ensembler** those derived using experimental techniques such as X-ray 384 also provides a stage for solvating models with explicit wacrystallography. RMS errors of \sim 3 Åfor C $_{lpha}$ atoms relative $_{^{385}}$ ter and performing a round of explicit-solvent MD refineto a native crystal structure are typical [25-27]. A num- 386 ment/equilibration under isothermal-isobaric (NPT) condiber of refinement methods have been developed to help 387 tions. The solvation step solvates each model for a given steer homology models toward more "native-like" confor- 388 target with the same number of waters to facilitate the inmations [26, 27], of which MD simulations are an impor- 389 tegration of data from multiple simulations, which is important example. While long-timescale unrestrained MD sim- 390 tant for methods such as the construction of MSMs. The ulations (on the order of 100 μ s) have been found to be in- 391 target number of waters is selected by first solvating each effective for recapitulating native-like conformations, pos- 392 model with a specified padding distance (default: 10 Å), sibly due to forcefield issues [25], even relatively short sim- 393 then taking a percentile value from the distribution (default: lations can be useful for relaxing structural elements such 394 68th percentile). This helps to prevent models with par-395 ticularly long, extended loops—such as those arising from template structures with unresolved termini—from imposing very large box sizes on the entire set of models. The TIP3P water model [32] is used by default, but any of the quality, this also prepares models for subsequent produc- 399 other explicit water models available in OpenMM, such as tion MD simulation, including solvation with explicit water 400 TIP4P-Ew [33], can be specified using the --water_model 401 flag. Models are resolvated with the target number of wa-Models are first subjected to energy minimization (using 402 ters by first solvating with zero padding, then incrementally 403 increasing the box size and resolvating until the target is ex-404 ceeded, then finally deleting sufficient waters to match the target value. The explicit solvent MD simulation is also im-406 plemented using OpenMM, using the Amber 99SB-ILDN force field [29] and TIP3P water [32] by default. The force field, water model, and simulation length can again be specified 409 using the --ff, --water_model, and --simlength flags 410 respectively. Further simulation parameters can be controlled via the API or via the CLI --api_params flag. Pres-⁴¹² sure control is performed with a Monte Carlo barostat as implemented in OpenMM, with a default pressure of 1 atm and pipeline to the human tyrosine kinase family indicated that 414 a period of 50 timesteps. The remaining simulation paramof the models which failed implicit solvent MD refinement, 415 eters have default values set to the same as for the implicit 416 solvent MD refinement.

Packaging

Ensembler provides a packaging module which 368 as implemented in the OpenMM package [2]. Any of 420 package_models subcommand currently provides func-

421 tions (specified via the --package_for flag) for compressing models in preparation for data transfer, or for organizing them with the appropriate directory and file structure for production simulation on the distributed computing platform Folding@home [4]. The module could 426 easily be extended to add methods for preparing models 427 for other purposes. For example, production simulations could alternatively be run using Copernicus [5]—a frame-429 work for performing parallel adaptive MD simulations— 430 or GPUGrid [6]—a distributing computing platform which relies on computational power voluntarily donated by the ⁴³² owners of nondedicated GPU-equipped computers.

Other features

433

434

441

453

454

Tracking provenance information

To aid the user in tracking the provenance of each model, 435 each pipeline function also outputs a metadata file, which helps to link data to the software version used to generate it (both **Ensembler** and its dependencies), and also provides timing and performance information, and other data such as hostname.

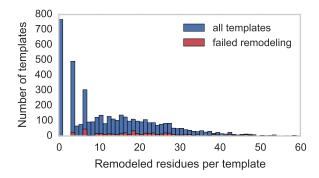

Rapidly modeling a single template

For users interested in simply using **Ensembler** to rapidly generate a set of models for a single template sequence, En**sembler** provides a command-line tool quickmodel, which performs the entire pipeline for a single target with a small number of templates. For larger numbers of models (such as entire protein families), modeling time is greatly reduced by using the main modeling pipeline, which is parallelized via MPI, distributing computation across each model (or across each template, in the case of the loop reconstruction code), and scaling (in a "pleasantly parallel" manner) up to the number of models generated.

III. RESULTS

Modeling of all human tyrosine kinase catalytic domains

As a first application of **Ensembler**, we have built models for all 90 human tyrosine kinase (TK) domains listed in UniProt. [JDC: Is there a complete list of these somewhere? Maybe reference supplementary data?] TKs (and protein kinases in general) play important roles in many cellular processes and are involved in a number of types of cancer. [JDC: CITE] For example, mutations of Src are associated with colon, breast, and prostate cancer [CITE: Src cancer involvement], while a translocation between the TK Abl1 and the 464 pseudokinase Bcr is closely associated with chronic myel- 487 465 ogenous leukemia [CITE: Abl1 cancer involvement]. Pro- 488 generally contain a significant number of missing residues 466 tein kinase domains are thought to have multiple accessi- 489 (median 11, standard deviation 13, max 102) due to the high

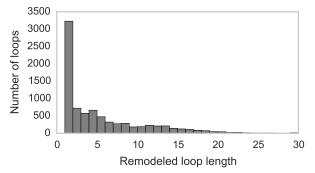

FIG. 2. Distributions for the number of missing residues in the **TK templates.** The upper histograms show the number of missing residues per template, for all templates (blue) and for only those templates for which template remodeling with the loopmodel subcommand failed (red). The lower histogram shows the number of residues in each missing loop, for all templates.

467 ble metastable conformation states, and much effort is directed at developing kinase inhibitor drugs which bind to and stabilize inactive conformations [34]. Kinases are thus a particularly interesting subject for study with MSM methods [CITE: recent kinase MSM papers], and this approach stands 472 to benefit greatly from the ability to exploit the full body of available genomic and structural data within the kinase 474 family, e.g. by generating large numbers of starting configurations to be used in highly parallel MD simulation.

We selected all available structures of protein kinase domains (of any species) as templates, for a total of 4433 (398,970 target-template pairs). The templates were de-479 rived from 3028 individual PDB entries and encompassed 23 different species, with 3634 template structures from human kinase constructs. [JDC: Shouldn't we state which options we used and what Uniprot searches we used for templates and targets? How would someone reproduce what we did here? Can we communicate this beyond just saying 485 "here are the scripts"?]

Ensembler modeling statistics

Crystallographic structures of kinase catalytic domains

490 mobility of several loops (Fig. 2, top), with a number of these missing spans being significant in length (median 5, standard deviation 6, max 82; Fig. 2, bottom). To reduce the reliance on the Modeller rapid model construction stage to reconstruct very long unresolved loops, unresolved template residues were first remodeled using the loopmodel subcommand. Out of 3666 templates with one or more missing residues, 3134 were successfully remodeled by the Rosetta loop modeling stage (with success defined simply as program termination with out error); most remodeling failres were attributable to unsatisfiable spatial constraints imposed by the original template structure. There was some correlation between remodeling failures and the number of missing residues (Fig. 2, top); templates for which remodeling failed had a median of 20 missing residues, compared to a median of 14 missing residues for templates for which remodeling was successful.

Following loop remodeling, the **Ensembler** pipeline was performed up to and including the implicit solvent MD refinement stage, which completed with 373,513 (94%) surviving models across all TKs. To obtain statistics for the solvation stage without generating a sizeable amount of coordinate data (with solvated PDB coordinate files taking up about 0.9 MB each), the solvate subcommand was performed for two representative individual kinases (*Src* and *Abl1*).

507

515

524

532

533

534

The number of models which survived each stage are shown in Fig. 1, indicating that the greatest attrition occurred during the modeling stage. The number of refined models for each target ranged from 4005 to 4248, with a median of 4160 and standard deviation of 60. Fig. 1 also indicates the typical timing achieved on a cluster for each stage, showing that the build_models and refine_implicit_md stages are by far the most compute-intensive.

Each model generated about 116 KB of file data (up to and including the implicit solvent MD refinement stage), totalling 0.5 GB per TK target or 41 GB for all 90 TKs. The data generated per model breaks down as 39 kB for the output from the modeling stage (without saving Modeller restraints files, which are about 397 kB per model) and 77 kB for the implicit solvent MD refinement stage.

Evaluation of model quality and utility

All tyrosine kinases

[JDC: DIscuss Fig. 3 first.]

To evaluate the diversity of conformations captured for each target sequence, we first computed the RMSD distributions for all models for each target (relative to the model derived from the highest-identity template) are shown in Fig. 4.

To better understand the influence of sequence identity on the conformational similarities of resulting models, the sequence identities were stratified based on the sequence identity distribution plotted in Fig. 3, which suggests an intuitive division into three categories, with 307.753 models

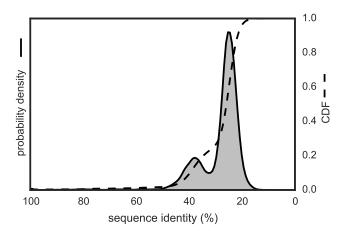

FIG. 3. Template-target sequence identity distribution for human tyrosine kinase catalytic domains. Sequence identities are calculated from all pairwise target-template alignments, where targets are human kinase catalytic domain sequences and templates are all kinase catalytic domains from any organism with structures in the PDB, as described in the text. A kernel density estimate of the target-template sequence identity probability density function is shown as a solid line with shaded region, while the corresponding cumulative distribution function is shown as a dashed line.

in the 0–35% sequence identity range, 69,922 models in the 545 35–55% range, and 4893 models in the 55–100% range. It is clear that higher sequence identity templates result in models with lower RMSDs, while templates with remote seguence identities result in larger RMSDs on average.

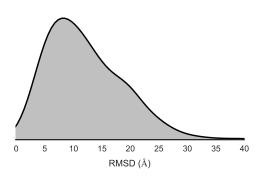

[JDC: This section looks pretty anemic. What other kinds of analyses can we do for all the TKs? There is so much data here! There must be something neat we can do to examine it, right?]

We also analyzed the potential energies of the models at the end of the implicit solvent MD refinement stage. These ranged from -14180 kT to -3590 kT, with a median of -9533 kT and a standard deviation of 1058 kT. The distributions—stratified using the same sequence identity ranges as above—are plotted in Fig. 5, indicating that higher sequence identity templates tend to result in slightly lower energy models. Of the 25,457 models which failed to complete the implicit refinement MD stage, all except 9 failed within the first 1 ps of simulation.

[DLP: for further analysis, a good option might be to try to make a more rigorous assessment of model quality via comparison to reference crystal structures, based on features such as RMSD, phi/psi angles, H-bonds etc. We could also try using the Rosetta heuristic scoring function for this purpose.]

Src and Abl1

identity distribution plotted in Fig. 3, which suggests an in- 570 To provide a more complete evaluation of the models tuitive division into three categories, with 307,753 models 571 generated, we have analyzed two example TKs (*Src* and *AbI1*)

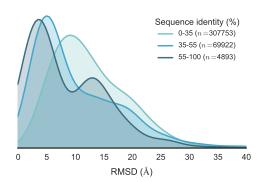

FIG. 4. Distribution of RMSDs to all TK catalytic domain models relative to the model derived from the highest sequence identity template. Distributions are built from data from all 90 TK targets. To better illustrate how conformational similarity depends on sequence identity, the lower plot illustrates the distributions as stratified into three sequence identity classes: high identity (55–100%), moderate identity (35–55%), and remote identity (0–35%). The plotted distributions have been smoothed using kernel density estimation.

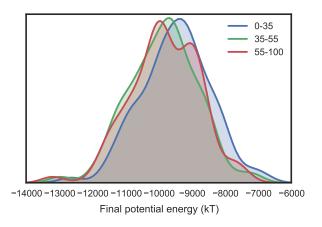

FIG. 5. Distribution of final energies from implicit solvent MD refinement of TK catalytic domain models. To illustrate how the energies are affected by sequence identity, the models are separated into three sequence identity classes: high identity (55–100%), moderate identity (35–55%), and remote identity (0–35%). The plotted distributions have been smoothed using kernel density estimation.

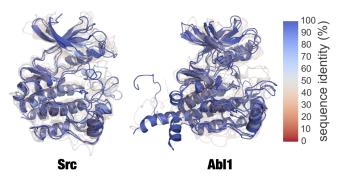

FIG. 6. Superposition of clustered models of Src and Abl1. Superposed renderings of nine models each for Src and Abl1, giving some indication the diversity of conformations generated by Ensembler. The models for each target were divided into three sequence identity ranges (as in Fig. 4), and RMSD-based k-medoids clustering was performed to select three clusters from each. The models shown are the centroids of each cluster. Models are colored and given transparency based on their sequence identity, so that high sequence identity models are blue and opaque, while lower sequence identity models are transparent and red.

in detail. Due to their importance in cancer, these kinases have been the subject of numerous studies, encompassing many different methodologies. In terms of structural data, a large number of crystal structures have been solved (with or without ligands such as nucleotide substrate or inhibitor drugs), showing the kinases in a number of different conformations. These two kinases are thus also interesting targets for MSM studies, with one recent study focusing on modeling the states which constitute the activation pathway of Src [35].

Fig. 6 shows a superposition of a set of representative models of Src and Abl1. Models were first stratified into three ranges, based on the structure of the sequence identity distribution (Fig. 3), then subjected to k-medoids clustering to pick three representative models from each sequence identity range. [JDC: Explain how k-medoids clustering was done either here or in figure caption.] Each model is colored and given a transparency based on the sequence identity between the target and template sequence. The figure gives an idea of the variance present in the generated models. High sequence identity models (in opaque blue) tend to be quite structurally similar, with some variation in loops or changes in domain orientation.

The Abl1 renderings in Fig. 6 indicate one high sequence identity model with a long unstructured region at one of the termini, which was unresolved in the original template structure. While such models are not necessarily incorrect or undesirable, it is important to be aware of the effects they may have on production simulations performed under periodic boundary conditions, as long unstructured termini can be prone to interact with a protein's periodic image. Lower sequence identity models (in transparent white or red) indicate much greater variation in all parts of the structure. We believe the mix of high and low sequence identity models to be particularly useful for methods such as MSM building, which require thorough sampling of the conformational

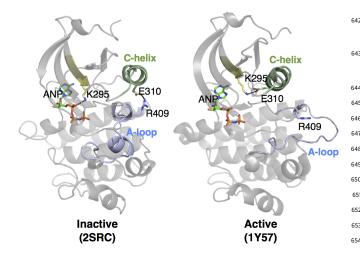

FIG. 7. Two structures of Src, indicating certain residues involved in activation. In the inactive state, E310 forms a salt bridge with R409. During activation, the α C-helix (green) moves and rotates, orienting E310 towards the ATP-binding site and allowing it to instead form a salt bridge with K295. This positions K295 in the appropriate position for catalysis.

608 landscape. The high sequence identity models could be considered to be the most likely to accurately represent true metastable states. Conversely, the lower sequence identity models could be expected to help push a simulation into regions of conformation space which might take intractably long to reach if starting a single metastable conformation.

To evaluate the models of *Src* and *Abl1* in the context of the published structural biology literature on functionally relevant conformations, we have focused on two residue pair distances thought to be important for the regulation of protein kinase domain activity. We use the residue numbering schemes for chicken Src (which is commonly used in the literature even in reference to human Src) [36, 37] and human Abl1 isoform A [38-40] respectively; the exact numbering schemes are provided in Supporting Information S1.

623

Fig. 7 shows two structures of Src believed to represent inactive (PDB code: 2SRC) [36] and active (PDB code: 677 states, depending on pH and on their local environment. 1Y57) [37] states. One notable feature which distinguishes 678 These protonation states can have important effects on bithe two structures is the transfer of an electrostatic inter- 679 ological processes. For example, long timescale MD simuaction of E310 from R409 (in the inactive state) to K295 (in 600 lations have suggested that the conformation of the DFG the active state), brought about by a rotation of the α C- α Chelix. These three residues are also well conserved [41], and 682 tory mechanism [CITE: Abl1 DFG flip evidence]—is controlled a number of experimental and simulation studies have sug- 683 by protonation of the aspartate [44]. Currently, protonation gested that this electrostatic switching process plays a role 684 states are assigned simply based on pH (a user-controllable in a regulatory mechanism shared across the protein kinase 685 parameter). At neutral pH, histidines have two protonation family [35, 42, 43]. As such, we have projected the **Ensem**- 686 states which are approximately equally likely, and in this sitbler models for Src and Abl1 onto a space consisting of the GBT uation the selection is therefore made based on which state distances between these two residue pairs (Fig. 8). The mod- 688 results in a better hydrogen bond. It would be highly deels show strong coverage of regions in which either of the 689 sirable to instead use a method which assigns amino acid electrostatic interactions is formed, as well as a wide range 690 protonation states based on a rigorous assessment of the of regions inbetween. We thus expect that such a set of mod- 691 local environment. We thus plan to implement an interels, if used as starting configurations for highly parallel MD 692 face and command-line function for assigning protonation simulation, could greatly aid in sampling of functionally rel- 693 states with MCCE2 [45–47], which uses electrostatics calcuevant conformational states.

AVAILABILITY AND FUTURE DIRECTIONS

Availability

The code for **Ensembler** is hosted on the collaborative open source software development platform GitHub,

http://github.com/choderalab/ensembler

The latest release of **Ensembler** can be installed via the conda package manager for Python [http: //conda.pydata.org]:

conda config -add channels https://conda.binstar.org/omnia

652 # conda ensembler

This will install all dependencies except for Modeller and Rosetta, which are not available through the conda package manager, and thus must be installed separately by the user. The latest source can be downloaded from the GitHub repository, which also contains up-to-date instructions for building and installing the code. [JDC: Where does documentation reside? And example inputs for generating 660 the results in this paper?]

Future Directions

JDC: In the Discussion, let's be sure to talk about the limitations and what could be improved or added in the future. For example, we don't yet handle counterions (e.g. structural Zn^{2+}), prosthetic groups (e.g. heme), or cofactors (e.g. ATP) yet. We don't handle post-translational modifications either (such as phosphorylation, methylation, glycosylation, etc.). It's a good idea to suggest that this is an important first step toward enabling superfamily- and genomicsscale modeling, but there's a lot of work yet to be done.]

Comparative protein modeling and MD simulation set-up can be approached in a number of different ways, with vary-673 ing degrees of complexity, and there are a number of obvious additions and improvements which we plan to imple-675 ment in future versions of Ensembler.

Some amino acids can exist in different protonation 694 lations combined with Monte Carlo sampling of side chain

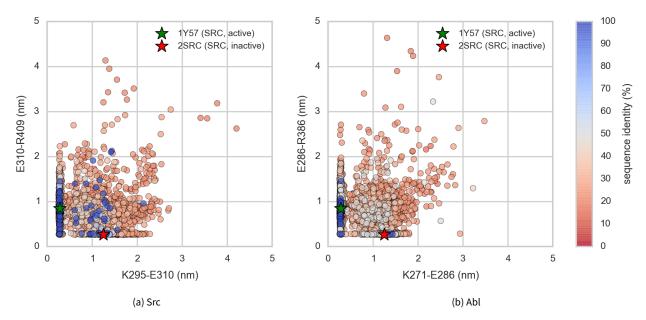

FIG. 8. Src and Abl1 models projected onto the distances between two conserved residue pairs, colored by sequence identity. Two Src structures (PDB entries 1Y57 [37] and 2SRC [36]) are projected onto the plots for reference, representing active and inactive states respectively. These structures and the residue pairs analyzed here are depicted in Fig. 7. Distances are measured between the center of masses of the three terminal sidechain heavy atoms of each residue. The atom names for these atoms, according to the PDB coordinate files for both reference structures, are—Lys: NZ, CD, CE (ethylamine); Glu: OE1, CD, OE2 (carboxylate); Arg: NH1, CZ, NH2 (part of guanidine).

695 conformers to calculate pKa values. [JDC: I think we may 725 want to consider doing that at this stage. Let's discuss.]

697

704

as metal ions (e.g. Mg^{+2}), cofactors (e.g. ATP) or posttranslational modifications (e.g. phosphorylation, methylation, glycosylation, etc.), and we thus plan for **Ensembler** to eventually have the capability to include such entities in the generated models. Binding sites for metal ions are frequently found in proteins, often playing a role in catalysis. For example, protein kinase domains contain two bindng sites for divalent metal cations, and display significantly 737 this. ncreased activity in the presence of Mg^{2+} [48], the divaent cation with highest concentration in mammalian cells. Metal ions are often not resolved in experimental structures of proteins, but by taking into account the full range of available structural data, it should be possible in many cases to include metal ions based on the structures of homologous proteins. We are careful to point out, however, that 738 metal ion parameters in classical MD force fields have significant limitations, particularly in their interactions with proteins [49]. Cofactors and post-translational modifications 739 and endogenous cofactors are frequently substituted with other molecules to facilitate experimental structural anal-724 tionality.

Another limitation with the present version of **Ensembler** 126 involves the treatment of members of a protein family with r27 especially long residue insertions or deletions. For example, Many proteins require the presence of various types of 728 the set of all human protein kinase domains listed in UniProt ion-protein atoms and molecules for proper function, such 729 have a median length of 265 residues and a standard deviation of 45, yet the minimum and maximum lengths are 102 and 801 respectively. The latter value corresponds to ⁷³² the protein kinase domain of serine/threonine-kinase *great*-₇₃₃ wall, which includes a long insertion between the two main 134 lobes of the catalytic domain. In principle, such insertions 735 could be excluded from the generated models, though a number of guestions would arise as to how best to approach

Conclusion

We believe **Ensembler** to be an important first step toare also often not fully resolved in experimental structures, ward enabling computational modeling and simulation of proteins on the scale of entire protein families, and suggest that it could likely prove useful for tasks beyond its original ysis. Again, **Ensembler** could exploit structural data from 743 aim of providing diverse starting configurations for MD sima set of homologous proteins to model in these molecules, 744 ulations. The code is open source and has been developed although there will be likely be a number of challenges to 745 with extensibility in mind, in order to facilitate its customizaovercome in the design and implementation of such func- 746 tion for a wide range of potential uses by the wider scientific 747 community.

ACKNOWLEDGMENTS

The authors are grateful to Kyle A. Beauchamp (MSKCC). 749 750 Robert McGibbon (Stanford), Arien S. Rustenburg (MSKCC) for many excellent software engineering suggestions. The authors thank Sonya M. Hanson (MSKCC), Nicholas M. Levinson (University of Minnesota), Markus A. Seeliger (Stony Brook), Diwakar Shukla (Stanford), and Avner Schlessinger

755 (Mount Sinai) for helpful scientific feedback on modeling ki-₇₅₆ nases. The authors are grateful to Benjamin Webb and Andrej Šali (UCSF) for help with the MODELLER package, Peter Eastman and Vijay Pande (Stanford) for assistance with OpenMM, and Marilyn Gunner (CCNY) for assistance with ⁷⁶⁰ MCCE2. DLP and this work was supported in part by the ₇₆₁ generous support of a Louis V. Gerstner Young Investigator 762 Award. [Add PBG support statement.]
